## Comparing Signaling Networks between Normal and Transformed Hepatocytes Using Discrete Logical Models

Julio Saez-Rodriguez<sup>1,2</sup>, Leonidas G. Alexopoulos<sup>1,2</sup>, MingSheng Zhang<sup>1</sup>, Melody K. Morris<sup>2</sup>, Douglas A. Lauffenburger<sup>2</sup>, and Peter K. Sorger<sup>1,2</sup>

### Abstract

Substantial effort in recent years has been devoted to constructing and analyzing large-scale gene and protein networks on the basis of "omic" data and literature mining. These interaction graphs provide valuable insight into the topologies of complex biological networks but are rarely context specific and cannot be used to predict the responses of cell signaling proteins to specific ligands or drugs. Conversely, traditional approaches to analyzing cell signaling are narrow in scope and cannot easily make use of network-level data. Here, we combine network analysis and functional experimentation by using a hybrid approach in which graphs are converted into simple mathematical models that can be trained against biochemical data. Specifically, we created Boolean logic models of immediate-early signaling in liver cells by training a literature-based prior knowledge network against biochemical data obtained from primary human hepatocytes and 4 hepatocellular carcinoma cell lines exposed to combinations of cytokines and small-molecule kinase inhibitors. Distinct families of models were recovered for each cell type, and these families clustered topologically into normal and diseased sets. *Cancer Res*; 71(16); 5400–11. ©2011 AACR.

### Major Findings

Clustering arises from systematic differences in signaling logic in three regions of the network. We also infer the existence of a new interaction involving Jak-Stat and NFκB signaling and show that it arises from the polypharmacology of an IκB kinase inhibitor rather than previously unidentified protein–protein associations. These results constitute a proof-of-principle that receptor-mediated signal transduction can be reverse engineered by using biochemical data so that the immediate effects of drugs on normal and diseased cells can be studied in a systematic manner.

### Introduction

The availability of high-throughput interaction data has led to the creation of methods for summarizing and exploring networks by using node–edge graphs. In these graphs, genes or proteins are represented by nodes (vertexes) and interactions by edges (3, 4). The underlying interaction data are diverse and include manual or automated text mining of the literature (5, 6), genetic interactions obtained from gene deletion sets, and physical interactions identified by large-scale mass spectrometry or 2-hybrid analysis (4, 7). Interactions in node–edge graphs can be undirected (denoting an unspecified interaction), directed but unsigned (denoting substrate–product relationships), or directed and signed (denoting both substrate–product and inhibition–activation relationships); the latter are particularly useful because they capture biochemical causality. For protein data, graphs comprising undirected edges are typically called protein interaction networks (PIN), whereas those with signed directed edges are known as protein signaling networks (PSN). Most work on PINs and PSNs to date has focused on adding as much data as possible, often from more than one organism or type of experiment, so as to construct large networks with the greatest possible scope and the greatest number of interactions per node (increasing the "degree" of the network); the culmination of this effort is a proposed "Human Interactome" covering all known gene products (8).

In cancer biology, comparative analysis is the natural focus of "conventional" low-throughput studies of signal transduction, with particular attention paid to differences in cellular responses to ligands or drugs in different cell types. In most cases, these differences reflect changes in the abundance or

**Quick Guide: Model Formalism and Training against Data**

We start with a prior knowledge network (PKN) comprising a "signed and directed" node-edge graph that depicts interactions among proteins as arrows so that substrate-product and activation-inhibition relationships are captured: Raf→MEK→ERK for example. The 78-node, 112-edge PKN in this article came from the Ingenuity database with manual additions. A PKN cannot be compared directly with cell response data because a model is needed to specify input-output relationships. Here, we use a simple Boolean formalism, in which the state of a node is either 0 or 1 ("off" or "on"), and nodes interact via AND/OR/NOT logical operators. In this formalism, if epidermal growth factor receptor OR IR is active, then MAP/ERK kinase (MEK) is active, etc. Conversion of a PKN into a Boolean model proceeds as follows. Network preprocessing specifies proteins to be measured or perturbed experimentally (so-called designated nodes) and then compresses the PKN on the basis of 2 criteria (1): a) nodes that are not directly or indirectly connected to designated nodes are eliminated (because we have no data on them; and b) cascades in which undesigned nodes impinge on designated nodes are simplified; for example, if Raf and ERK are designated, but MEK is not, then Raf→MEK→ERK is replaced by Raf→ERK. Logical expansion computes all possible combinations of logic gates compatible with the compressed network. Each interaction in the PKN (hyperedges in graph theory) can give rise to multiple logical connections, so that if 2 edges link into ERK (e.g., Raf→ERK and NFκB→ERK), we would generate 3 logical interactions: (i) Raf→ERK, (ii) NFκB→ERK, and (iii) Raf AND NFκB→ERK. An OR gate (Raf OR NFκB→ERK) simply corresponds to (i) plus (ii). In our compressed PKN, 32 nodes and 128 logical interactions (hyperedges) give rise to  $2^{128} = \sim 10^{38}$  possible models, each of which is evaluated against data. Training a family of possible models against data involves propagating the input signals along the logical network until all nodes reach interconsistent values (a logical steady state); models are then compared with experimental measurements. Raw data are processed so that arbitrary intensity measures from xMAP sandwich immunoassays are converted into values between 0 and 1 on the basis of various standards, a procedure that we have previously described in detail (1). For quantitative analysis of model/data match, the deviation [mean squared error (MSE)] between data and a specific model is computed as  $MSE = \frac{1}{n_E} \sum_{k=1}^s \sum_{l=1}^m \sum_{t=1}^n \left( B_{k,l,t}^M - B_{k,l,t}^E \right)^2$ , in which  $B_{k,l,t}^M \in \{0, 1\}$  is predicted by the logical steady state of the model and  $B_{k,l,t}^E \in (0, 1)$  is the discretized data for assay  $l$  recorded at time  $t$  under the  $k^{th}$  experimental condition. Values incompatible with a logical steady state are penalized as though they represent a mismatch between simulation and experimental data. We seek the simplest models consistent with data, using a bipartite objective function:  $\Theta = MSE + \alpha \Theta_s$ , in which  $\Theta_s$  is model size and  $\alpha$  is an adjustable parameter. We have shown that models identified using this objective function are similar in their numbers of edges and goodness of fit across a wide range of values for  $\alpha$  (1); in this article, we set  $\alpha = 0.0001$ .

The training procedure consists of searching across  $2^{128}$  models with the objective function by using a standard genetic algorithm (2). Model training was iterated 50 to 100 times for each set of data. Because of the stochastic nature of the genetic algorithm and the nonidentifiability of the models given data, different solutions were recovered each time. In common with most work on network inference, we addressed nonidentifiability by analyzing families of models instead of single solutions; in this work, models within 1% MSE of the best-fit model constituted the "consensus." For subsequent analysis, the distance between 2 sets of models  $j$  and  $k$  was computed as  $d_{j,k}^2 = \sum_{i=1}^n \left( f_i^j - f_i^k \right)^2$ , in which  $f_i^k$  is the frequency of the  $i^{th}$  hyperedge in the  $k^{th}$  model set. Distances were normalized with respect to the distance between hepatocyte and AvgHCC models (Supplementary Table S1).

activity of signaling proteins (or of their substrates), features that could in principle be depicted by the strength of an edge in a network graph. However, existing PSNs and PINs do not encode the activities of proteins in cells that have been exposed to specific activators or inhibitors. A dearth of data on context-specific interactions makes it difficult to compare normal and diseased cells, or diseased cells from different tumors. Cell- and state-specific information has been added to network graphs using gene expression data (3, 7, 9), but few attempts have been made to reconstruct comparative networks using biochemical data.

In this article, we attempt to combine concepts from global network discovery and traditional biochemistry by constructing comparative network models of signal transduction in normal and transformed liver cells. Starting with a prototypical network derived from the literature [which we will refer to as a prior knowledge network (PKN)], we first constructed a set of

all Boolean models compatible with the PKN, used the model "superstructure" to guide the collection of biochemical data on multiple nodes in the network across multiple cell types, and then trained the superstructure against data to uncover underlying differences in signaling logic among cell types. The net result is a computational representation of a signaling network that focuses on activity rather than literature association or physical interaction and that is explicitly comparative.

A first essential step in adding activity data to networks is to convert PKNs into models in which it is possible to compute input-output characteristics (1). In this article, we use a 2-state (Boolean) logical formalism in which each node can have only two states, 0 or 1, but having a 1 at the output can depend on having a 1 at one of several inputs (an OR gate), all inputs (an AND gate), or 0 and 1 inputs in any combination. Boolean models have the advantage that they have no continuous free parameters and their topologies can be trained

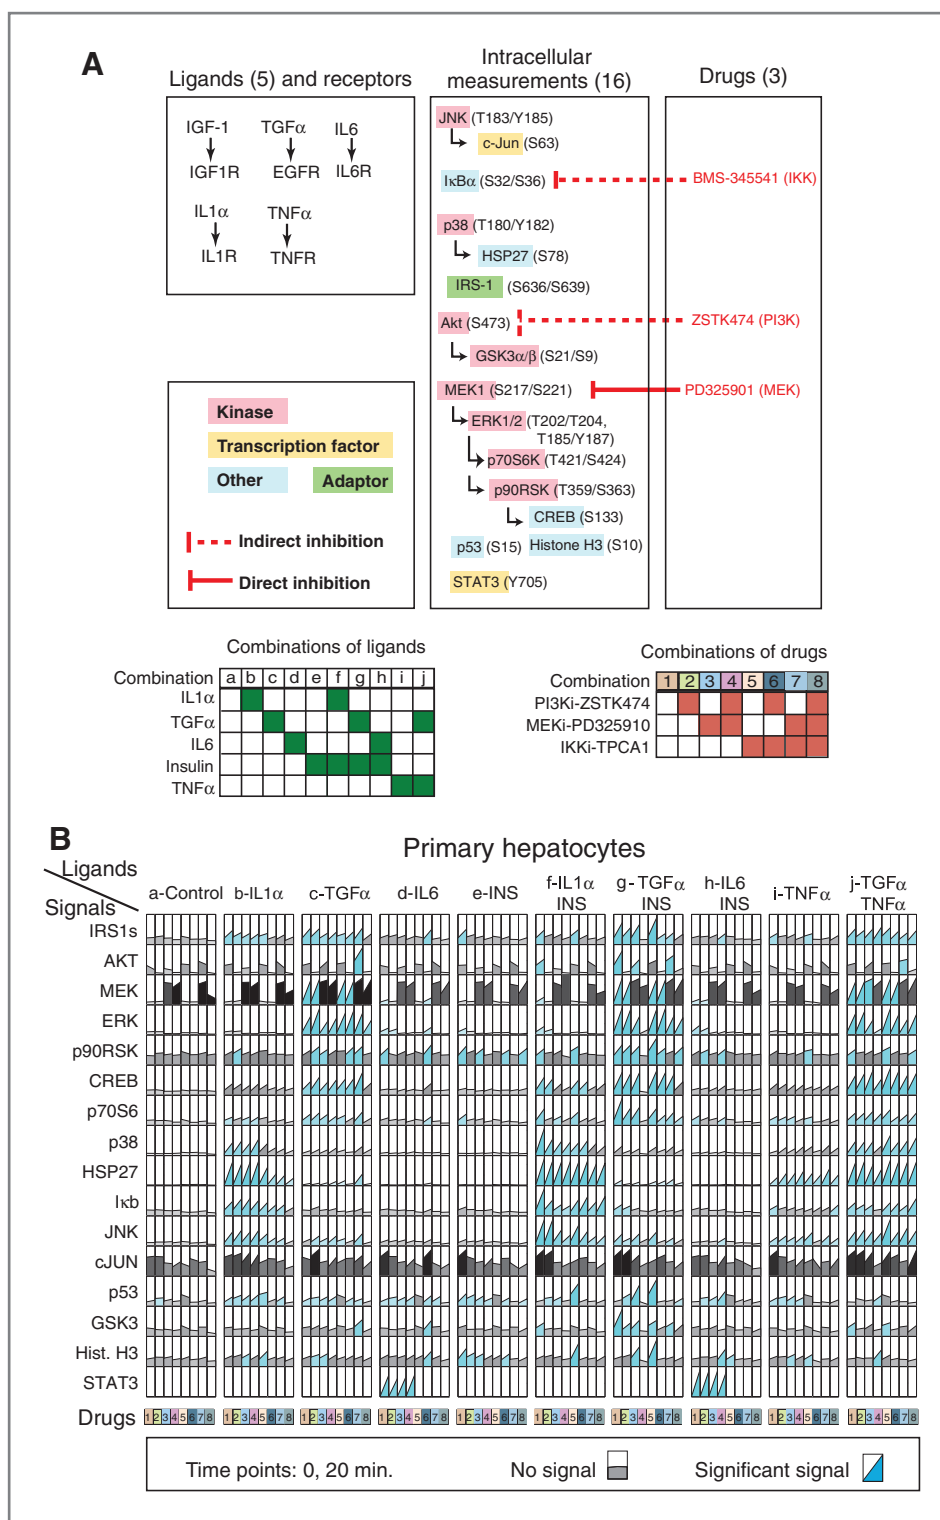

Figure 1. Experimental design and primary data. A, outline of the experimental approach showing 5 ligand cues and their receptors, 16 intracellular "signals" assayed using phospho-specific antibodies and xMAP technology (the relevant phosphorylated residues are indicated, as are the likely upstream kinases), and 3 small molecule kinase inhibitors. B, dataset from human hepatocytes. Rows represent intracellular signals assayed immediately prior to ligand addition and 25 minutes thereafter, and columns represent different ligand combinations (see legend). For each combination of ligands, 1 of 3 kinase inhibitors was applied, as well as all possible combinations of them. Data are color coded to highlight induction (relative to basal activity).

efficiently using data (1), a task that is harder with large differential equation models (10). However, we recognize that real biological systems exhibit dose response behavior that is only poorly approximated by Boolean logic. Thus, a major question at the outset of this work was whether the strengths

of Boolean modeling with respect to computational simplicity would outweigh its weaknesses. It seemed possible that the crudeness of the Boolean on/off approximation would overwhelm any differences we might measure experimentally from one cell type to the next. Conversely, success in creating

Figure 1. (Continued) C, data from HepG2 cells following the same design as in A. The intensity of background color for each box (yellow to red) indicates how the proportion of tumor cell lines that also responded to a particular drug–ligand combination; complete data can be found in Supplementary Fig. S1. Data were processed using *DataRail* software (18).

comparative models would constitute a proof-of-principle for the approach.

We therefore applied Boolean modeling to distinguishing patterns of immediate-early signaling in normal and transformed cells, represented here by primary human hepatocytes and HepG2, Hep3B, Focus, and Huh7 liver cancer cell lines. Liver cancer (which is dominated by hepatocellular carcinoma [HCC]) is the third most common cause of cancer death in humans (11) and is known to involve alterations in the EGF-Ras-MAPK, AKT-mTOR, Jak-Stat, and NF- $\kappa$ B cascades (12). Thus, we aimed to collect multivariate data on the activities of these pathways in normal and transformed hepatocytes. We show that it is possible to assemble predictive network models that are specific to each cell type, cluster models based on topology, and uncover consistent biochemical differences between transformed and normal cells. By identifying an interaction missing from the starting PKN, but supported by data, we also uncover a poorly documented off-target effect of a drug being developed for asthma and inflammation (13, 14). Our findings show that discrete logical modeling can capture cell-type specific biochemical relationships, raising the possibility of constructing large comparative models of signal transduction in normal and diseased cells.

## Materials and Methods

### Data generation

HepG2 and Hep3B, Huh7, and Focus cells were plated in 96-well plates coated with collagen type I (Becton Dickinson) with 100  $\mu$ L phenol-free Williams' Medium E (WEM; Sigma-

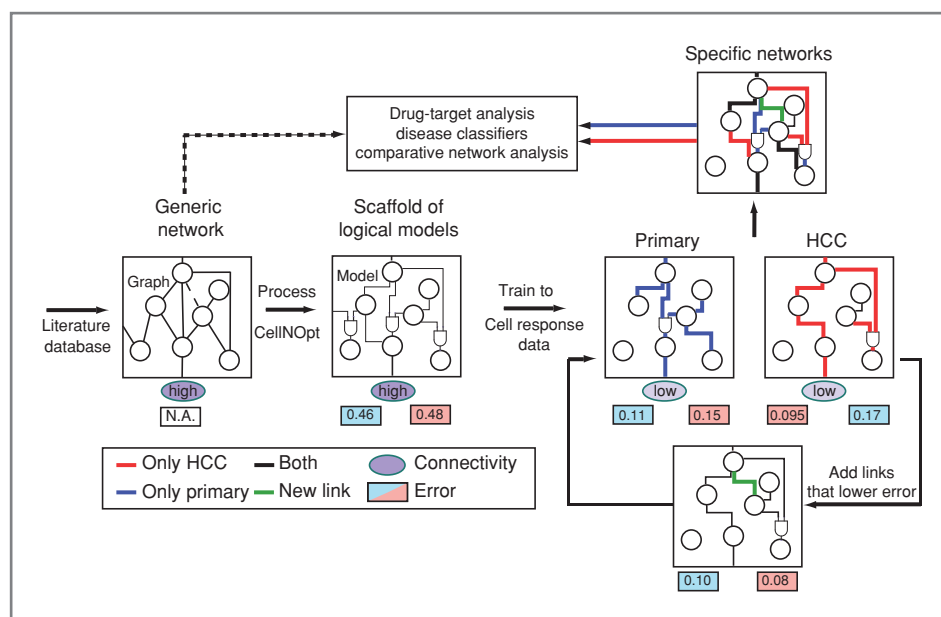

Aldrich) with supplements (15). Freshly preplated primary human hepatocytes were purchased from CellDirect and cultured overnight on collagen, starved for 6 hours in 95  $\mu$ L of WEM, exposed to kinase inhibitors for 40 minutes, and then to ligands for 25 minutes. All cells were lysed in 90  $\mu$ L of manufacturer's xMAP buffer (Bio-Rad) and intracellular signals measured by using a Luminex Instrument (Luminex) and 16-plex phosphoprotein bead sets (Bio-Rad; see Supplementary Material). Different dilutions of cell extract were required for all 16 signals to be in the linear range.

HepG2 and Hep3B cell lines were obtained directly from American Type Culture Collection (ATCC); Huh7 and Focus cells (16), which are not available from ATCC, were obtained from Prof. Jack Wands (Brown University, Providence, RI). Cells were expanded once to create master stocks from which working cultures were periodically established; no lines were serially passaged longer than 3 weeks. ATCC cell lines are validated by the provider (17); no testing was carried out on the other lines. Freshly plated human hepatocytes were tested for contaminants as described in ref. 15.

### Reagents

To minimize experimental variability, samples were processed in parallel and common stocks of cytokines, inhibitors, and assay reagents used throughout (see Supplementary Materials). Recombinant Jak2 and IKK-2 obtained from Cell Signaling Technology were preincubated with kinase inhibitors for 5 minutes in manufacturer's buffer with 20  $\mu$ M ATP and FLT3 as Jak2 substrate or Ikb as a IKK-2 substrate. Phosphorylation was assayed by using a time-resolved fluorescence plate reader (PerkinElmer Victor 3) and

**Figure 2.** General workflow and goodness of fit of the cell-specific models. Schematic of workflow of model assembly, training, validation, and extension. A PKN derived from interaction data is imported into *CellNOpt* and converted into an assembly of all possible logical interactions. The assembly is then trained against experimental data, generating cell-specific models having lower MSE error. In general, this involves removing interactions present in the PKN that are not supported by the data. Interactions absent from the PKN can then be added to see whether they reduce residual error (green line). Once a satisfactory model is found, it is analyzed to identify differences among cell lines.

apparent  $IC_{50}$  calculated from the activity  $A$ , in which  $A = (I + [drug]/IC_{50}^H)^{-1}$  and  $H$  is the apparent Hill coefficient.  $K_i$  for TPCA-1 was calculated by using the Cheng-Prusoff equation,  $K_i = IC_{50}/(1 + [ATP]/K_M)$ , in which  $K_M$  (for ATP) was 0.43  $\mu\text{mol/L}$  for Jak2 and 0.91  $\mu\text{mol/L}$  for IKK-2.

### Data handling

Data were processed and visualized using *DataRail* software (18, 19), with xMAP measurements normalized to a value between 0 and 1 (1).

### Network construction and model calibration

The starting PKN was constructed with ProMoT (20) using the database of Ingenuity Systems (21) supplemented manually. Modeling was then done using our MATLAB toolbox *CellNetOptimizer* (*CellNOpt*; ref. 22).

### Results

The dynamics of immediate-early signaling pathways were probed by using a combinatorial experimental protocol (23): primary human hepatocytes and 4 HCC lines were treated with Interleukin (IL)-1 $\alpha$ , IL-6, TGF- $\alpha$ , TNF- $\alpha$ , and insulin (15), in the presence and absence of small-molecule kinase inhibitors of IKK, MAP/ERK kinase (MEK), and phosphoinositide 3-kinase (PI3K), and 16 intracellular signaling proteins were then assayed in cell extracts using multiplex sandwich immunoassays (xMAP assays; Lumindex Inc. Fig. 1 and Supplementary Fig. S1; ref. 15). Our use of kinase inhibitors and phosphoprotein antibodies naturally focused the analysis on the druggable kinome (24), but similar analysis with other classes of drugs and signaling proteins is also possible. The experiments generated 5 sets of ligand-response data (for HepG2, Focus, Hep3B, and Huh7 cell lines; "hepatocytes" refers to primary human hepatocytes); a sixth dataset (AvgHCC) was synthesized by arithmetically averaging data from the 4 tumor

lines and attempts to capture biochemistry common to all cell lines.

All Boolean models compatible with a PKN of receptor-mediated signaling that included 78 nodes and 112 interactions was processed using freely available software of our own design, *CellNetOptimizer* (*CellNOpt*; ref. 1). This yielded an ensemble of approximately  $10^{38}$  models having 128 AND or OR gates with different connectivity or logic. The ensemble of models was compared with each of 6 sets of experimental data (representing 5 cell types and the average) using a bipartite objective function that minimized the deviation between model and data while penalizing model size (Fig. 2). For any single dataset, optimization returned multiple models that differed slightly in topology and logic but had nearly the same value of the objective function (therefore making them indistinguishable with respect to data). Such "nonidentifiability" is common in network inference, and we therefore retained a family of best-fit models for each cell type differing by 1% in goodness of fit (see Quick Guide box for details).

Because Boolean models lack continuous parameters (akin to the rate constants in an differential equation network), it is not necessarily true that training will yield a model having a substantially better fit to data than the PKN, but this was the case with our data and models: The untrained ensemble containing all possible interactions and logic exhibited a poor fit (39%–47% MSE error across all datasets, Fig. 3), whereas families of trained models exhibited much better fit (9%–13% MSE error, see Fig. 3 and Supplementary Fig. S2). We carried out cross-validation and statistical tests to show that trained models were predictive of real data and were nonrandom (Supplementary Figs. S3–5). Moreover, models trained against individual HCC cell lines were all better than the starting ensemble at predicting AvgHCC data (which was not used in training; 10%–14% MSE error, Fig. 3A). When the fit between models and data corresponding to individual ligands or biochemical assays was examined, levels of error were

**Figure 3.** Residual error (MSE deviation; see Materials and Methods) of the models. **A**, MSE for the ensemble of all possible models compatible with the PKN and pairwise combinations of trained, cell-specific models with various datasets. The magnitude of the error is mapped to the intensity of the background (with red highest). Trained models fit corresponding data best, but all trained models exhibit lower error with all datasets than the starting ensemble. **B**, average MSE error of models across all cell types for specific experimental conditions and biochemical assays. For a single experiment, the error varies between 0 and 1; the maximal error was observed for phospho-STAT3 in cells treated with IL-6 (MSE  $\sim$ 0.4).

relatively low except in the case of p53 and IRS1s, which exhibited poor fits across all conditions (Fig. 3B and Supplementary Fig. S6). This almost certainly arises because the PKN represents p53 biology in an imprecise manner and annotation of IRS1 modification is incomplete. These are areas in which improved PKNs would clearly be useful. Nonetheless, we conclude that model training recovers substantially better network representations than the starting PKN.

#### Signaling network properties determined from data-trained logical models

In our procedure, training a PKN-based Boolean model against data improves the goodness of fit by removing unused edges. However, connectivity varied significantly with cell type: 85 of 128 possible gates were present in the superposition of all models in all cell types (involving  $\sim$ 90% of the interactions not removed in the preprocessing), but only 7 gates were common to all models (Fig. 4 and Supplementary Fig. S7). We therefore concluded that the primary deficiency of the literature-derived PKN with respect to our data is not the presence of true false-positive interactions (because some support can be found for most edges in data) but rather an absence of cell-type specificity.

To compare the topologies of models for all 6 datasets, we computed pairwise distances by enumerating edges that differed between averaged best-fit models (see Materials and Methods and Supplementary Table S1 for details). HCC-derived models clustered together, with models built from AvgHCC data in the middle of the cluster, and well separated from models of primary hepatocytes (Fig. 5A). Models of Focus cells were farthest from primary cell models and HepG2 models were closest, in agreement with a classification of HCC lines proposed previously (25–27; Fig. 5B). Moreover, the pattern of clustering derived from network topology was generally similar to the pattern computed from transcriptional profiles. Although the goal of logical modeling

is not to generate cluster diagrams (being focused instead on the biochemistry of signal transduction), the similarities between clusters generated using transcript profiling and logical models suggest that the biochemical processes covered in our networks are representative of broader differences across cell lines.

#### Pathway differences in signaling networks among primary and transformed cells

Next, we asked which interactions or logical gates were consistently present or absent when all possible models for one cell type were compared with all models of another cell type. This is a conservative approach that accounts for the inability of training to uniquely specify a model for each cell type on the basis of available data. We observed that 1 interaction was absent from all models of HCC cells although being present in all models of primary hepatocytes, whereas 6 interactions had the opposite property, being present only in models of HCC cells (Fig. 6). These differential interactions affected 3 regions of the signaling network. First, whereas the epidermal growth factor receptor (EGFR) ligand TGF- $\alpha$  caused ERK activation in all cell types, upregulation of Hsp27-S78 phosphorylation (presumably by PRAK kinase, which lies downstream of ERK) was observed only in primary cells (differential interactions 1–2). In 2 of 4 HCC cell lines (Focus and Huh7), Hsp27-S78 was phosphorylated to a significant degree, but it was p38- rather than ERK dependent (Supplementary Fig. S7). These findings are consistent with a reported association between low levels of Hsp27-S78 phosphorylation and tumor progression in HCC; our data show that the situation is more complex than previously thought (28), potentially involving a switch in Hsp27 kinases. A second significant difference between primary and HCC cells involved a change in the inferred logic of the IKK-NF- $\kappa$ B pathway: In primary hepatocytes Ikb-S32/S36 phosphorylation (a signal for Ikb degradation and consequent nuclear localization

**Figure 4.** Inferred models of immediate-early signaling in primary and transformed hepatocytes. The graph represents nodes and edges present in a set of trained Boolean models deviating by 1% in MSE and considered to be indistinguishable. The graph was created by exporting a GraphML file from from ProMoT (20) and modifying it with GraphViz (48). Line thickness denotes the frequency OR-gated edges found in trained models of primary hepatocytes (blue) or an average of the 4 HCC models (red); solid black edges were found in both primary and HCC cell lines. Thin gray edges were absent from all models, and dashed gray edges removed in the network preprocessing step (1). Green hexagons denote stimuli, red rectangles targets of kinase inhibitors, and blue rectangles readouts. Rectangles with magenta fill were both measured and subjected to inhibition using small molecule drugs. Rectangles with white fill were compressed during graph processing. An AND gate is present upstream of IKK only in models of primary hepatocytes (see text); no other AND gate was consistently identified. The dashed black line denotes an interaction missing from the starting PKN but whose inclusion reduced the MSE of both hepatocyte and HCC models. This interaction implies inhibition of Stat3 phosphorylation by IKK in IL-6-stimulated cells (see text).

of NF- $\kappa$ B) required TNF- $\alpha$  and an activator of PI3K such as TGF- $\alpha$  (differential interactions 3–4). In contrast, in HCC lines only TNF- $\alpha$  was required, implying differential control over canonical NF- $\kappa$ B-mediated signaling.

The third significant difference involved phosphorylation of PI3K/AKT and GSK3-S9/S21 in insulin-treated HCC cells but not in primary hepatocytes (differential interactions 5–8). AKT is a potent prosurvival kinase, and its phosphorylation of GSK3 on S9/S21 is known to downregulate GSK3 activity and promote nuclear localization of  $\beta$ -catenin, NFAT, and other progrowth factors (29). Insulin receptor (IR) substrate 1 (IRS1) is overexpressed in HCC cell lines (30), and it is possible that this shifts IR signaling (or signaling by insulin-like growth factor receptors, which are also present in these cells) from a metabolic function in normal liver (31)

to a prosurvival function in tumors that involves elevated PI3K/AKT and GSK3 phosphorylation. Increased AKT activity is also expected in tumors due to downregulation of proteins such as the p85 subunit of PI3K, a common feature of HCC (32).

Overall, we conclude that direct comparison of Boolean models was successful in identifying activity-dependent differences among normal and diseased cells that are hard to capture in PINs and PKNs assembled from physical interaction or steady-state proteomic and expression data. At the same time, we note that the Boolean models in this article capture signaling at a single time point only, and only describe ligand-driven changes in phosphorylation. The absence of an IR $\rightarrow$ PI3K link in the inferred map for hepatocyte signaling (despite the known function of IR in the liver; ref. 32) might

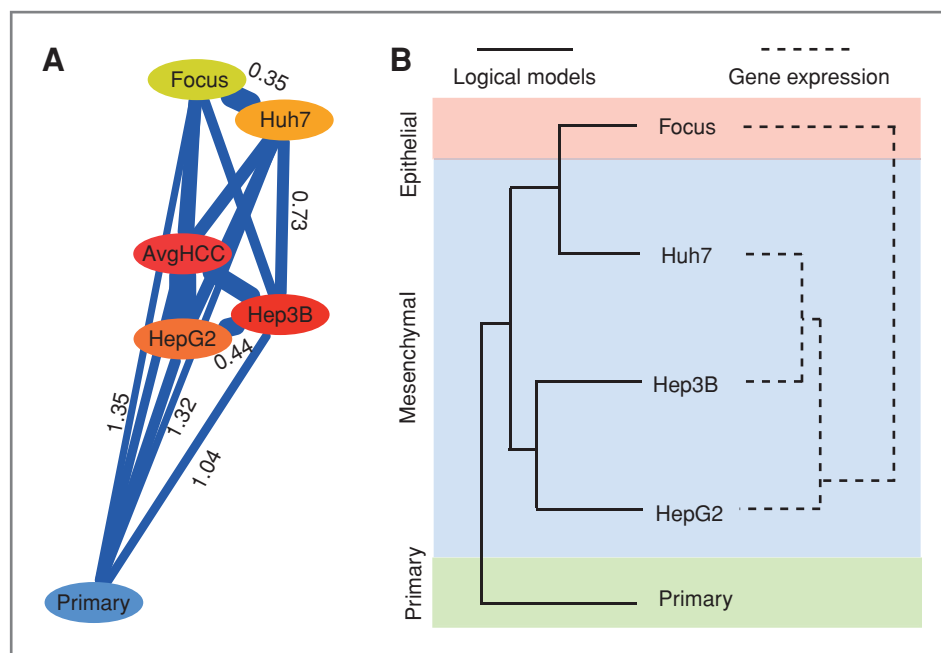

Figure 5. Topological clustering of logic-based models of primary and transformed hepatocytes. A, distances between primary hepatocytes and the 4 HCC cell lines (Huh7, Focus, Hep3B, and HepG2) and a "average HCC cell line" (AvgHCC) based on the mean difference in the topologies of Boolean models as defined by the distance  $d^L$  (see Methods) and plotted by using the edge-weighted spring embedded algorithm in Cytoscape (49). The full range of distances is listed in the Supplementary Materials. B, hierarchical clustering of primary and transformed hepatocytes based on the logical models, and a comparison to previous published clusters based on gene expression (the dendrogram was manually redrawn from reference 26 and distances are approximate). A classification of cell lines as epithelial or mesenchymal (25) is also shown (see Supplementary Fig. S8).

arise because basal levels of AKT phosphorylation are high in these cells, making it difficult to detect ligand-dependent superactivation, or because we assayed cells at the wrong point in time (methods for incorporating time-series data into calibrated Boolean models are in development). However, Boolean modeling correctly inferred an  $EFGR \rightarrow PI3K$  link in both transformed and primary cells and follow-up experiments suggest that there is indeed a greater propensity of tumor cells to respond to insulin by activating AKT.

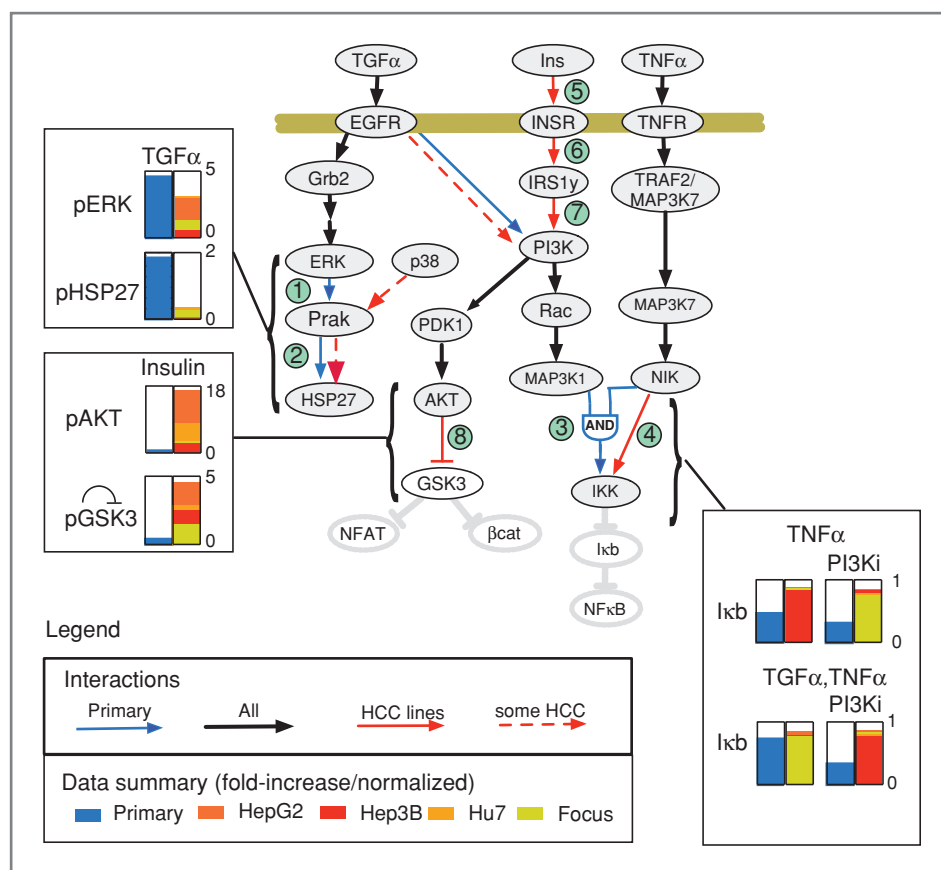

#### Identification and testing of model-inferred novel pathway interactions

The model training described above focused on eliminating interactions present in the PKN but not supported by data. However, it is likely that PKNs also lack interactions that are supported by data. Indeed, we observed that the single largest error in all models with respect to data involved an observed inhibition of Stat3-Y705 phosphorylation by the IKK inhibitor TPCA-1 under conditions of IL-6 stimulation (Fig. 3B). TPCA-1 is reported to be a potent and selective inhibitor of human Ikbkinase-2 ( $IC_{50} = 18$  nmol/L for IKK-2 and 400 nm for IKK-1) and was originally identified by GlaxoSmithKline in a drug discovery effort focused on rheumatoid arthritis and airway inflammation (13, 14). The inhibition of Stat3-Y705 phosphorylation by TPCA-1 can be explained in a Boolean model by adding an interaction between IKK and Stat3 (see Fig. 4); this reduced the MSE error of all model families by approximately 5%. Whereas an  $IKK \rightarrow Stat3$  edge might represent a physical

interaction, an alternative explanation is that prior knowledge about TPCA-1 is incorrect and the drug actually inhibits Jak2, the known kinase for Stat3. To distinguish among these possibilities, we carried out *in vitro* activity assays of purified Jak2 and IKK-2 in the presence of TPCA-1 or BMS345541, an IKK-2 inhibitor having a distinct chemical structure ( $IC_{50} \sim 300$  nmol/L). BMS345541 does not compete with ATP (it binds to homologous allosteric sites on IKK-1 and IKK-2) and presumably has different off-target effects. We found TPCA-1 to be nearly as potent an inhibitor of Jak2 *in vitro* ( $K_i \sim 9$  nmol/L) as of IKK-2 ( $K_i \sim 1.6$  nmol/L), its known target, but BMS345541 was IKK selective. Moreover, in IL-6-stimulated cells, BMS345541 reduced phosphorylation of the IKK substrate Ikb $\alpha$  on Ser32/Ser36 but had no detectable effect on the level of phosphorylated Stat3-Y705 (Fig. 7). We conclude that Jak2 is a target of TPCA-1 (consistent with a recent kinome profile; ref. 33), and that Boolean network inference therefore identified a new target for the drug rather than a new protein-protein interaction.

#### Discussion

Despite the relative crudeness of 2-state logical approximations of biochemical reactions, this article shows that it is possible to use Boolean modeling in combination with high-throughput cell-response data to automate discovery of biochemical differences in signal transduction among tumor and normal cell types. Applying the approach to primary

**Figure 6.** Key differences uncovered by logic-based modeling. Schematic of inferred differences between HCC cell lines and hepatocytes. The callouts show data associated with each topological difference. Fold increases in measured values are shown. In the case of I $\kappa$ B, normalized data are shown (this is the form of the data used for model calibration). Numbered green circles label differences between primary and HCC cells. Fold increase in actual values are shown, except in the case of I $\kappa$ B, in which normalized data are compared with predictions from Boolean models (for clarity). Numbered green circles label differences between primary and HCC cells.

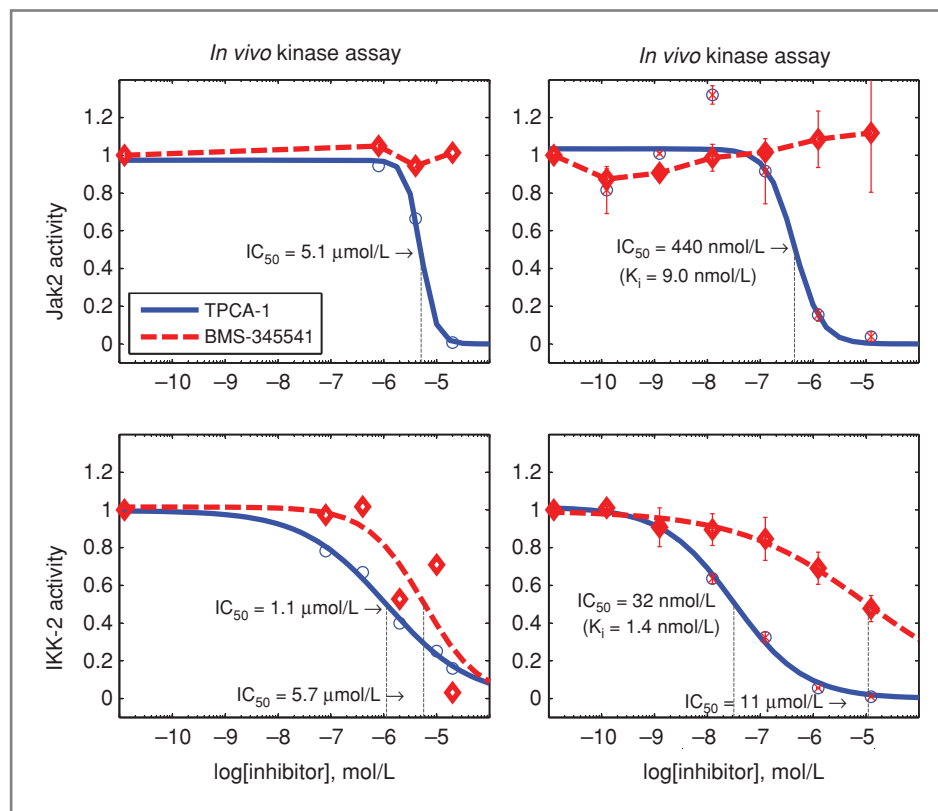

human hepatocytes and 4 HCC cell lines revealed consistent differences in the apparent logic and activities of growth factor receptor and intracellular kinase cascade in response to different ligands. Among the inferred differences between normal and transformed cells are several involving the strength or logic of signaling among IR, PI3K, AKT, and NF- $\kappa$ B, all molecules that have been implicated in the development of HCC. An unexpected pharmacologic insight was the identification of Jak-Stat signaling as a target for TPCA-1, an I $\kappa$ B kinase inhibitor developed to treat arthritis and airway inflammation. Detecting this polypharmacology required comparison of a computable network model against data across a landscape of treatment conditions, thereby allowing multivariate effects to be linked to specific causes. Intriguingly, TPCA-1 is significantly more potent than other IKK inhibitors in assays for airway inflammation. Both Jak2/Stat3 and IKK/NF- $\kappa$ B play a role in inflammation (13, 14) and TPCA-1 would therefore seem to be a "dirty" drug that is superior to a drug that binds specifically to the nominal target (34). More generally, the approach to modeling described in this article may constitute a general means to study polypharmacology that is complementary to methods for investigating drug mechanism on the basis of transcriptional data and protein interaction networks (35).

Our method focuses on eliminating interactions in the PKNs that do not fit data. Because the number of potential edges in an approximately 80-node network exceeds  $10^{10}$ , it is

currently impossible to conduct a comprehensive search for new edges that improve the fit to data. However, in the current work simple inspection sufficed to identify a potential AND-gated edge connecting IKK $\rightarrow$ Stat3 that was absent from the PKN. Implementing a rigorous approach to finding new edges will require efficient means to search models locally or to make more intelligent use of prior knowledge. Alternatively, a variety of network-inference methods other than Boolean logic are likely to be effective for analyzing biochemical data, including differential equations (36–38), Bayesian networks (39), and fuzzy logic (40). Continued development of *CellNOpt* on our part, as well as the creation of alternative modeling approaches fostered by efforts such as DREAM (41), is likely to improve the efficiency and accuracy of network inference from biochemical data. Moreover, improvements in affinity capture assays, protein arrays (42), and mass spectrometry (43, 44) should make it possible to collect much more extensive training data than we report here.

Deep sequencing and other approaches to genome analysis support the idea that it is networks and pathways rather than individual genes that are the functional objects of oncogenic mutation and selection in human cancer (45). However, approaches for constructing large-scale protein interaction graphs (4–6) are rarely cell-type specific, and traditional "bottom-up" experiments that focus on cellular responses rather than network topologies are effective at uncovering

Figure 7. Probing the biochemistry of an inferred IKK-Stat3 interaction. For *in vivo* experiments, cells were pretreated with 2 to 20  $\mu\text{mol/L}$  TPCA-1 or BMS345541. The concentration range of TPCA-1 was 10-fold lower than BMS345541 to match published  $\text{IC}_{50}$  values for inhibition of I $\kappa$ b phosphorylation. Cells were pretreated with drug for 1 hour and then stimulated with IL6; the phosphorylation of Stat3Y705 was measured 25 minutes thereafter. *In vitro* experiments were conducted with recombinant kinases and phosphorylation levels measured by using a fluorescence assay.

such differences, but they cannot easily incorporate network information in a formal way. Comparative network inference is needed to close the gap, but current efforts focus on gene regulatory networks, in large part because available datasets involve expression signatures, gene sequences, and transcription factor binding sites (9, 46). Our results with Boolean logic and biochemical data constitute an encouraging proof-of-principle that the biochemistry of signaling networks, including the states and activities of proteins important in modern drug discovery, can be also be inferred and studied systematically. Because the product of our analysis is a computable model, it is amenable to continuous improvement and extension (with new data and interactions, for example) in much the same way as networks inferred from genome data. In contrast, it is difficult to account for new data by using conventional, informal descriptions.

However, comparison of contemporary approaches to studying gene regulatory network in cancer (e.g., Carro and colleagues; ref. 9) with our work serves to illustrate a fundamental difference between genome-scale data and "high throughput" biochemistry. Genomic datasets tend to contain many data points, and identifying regulatory interactions and biologically meaningful covariation is a major challenge. In contrast, even "systematic" sets of biochemical data are much smaller. However, biochemical data are also preselected to contain relevant signaling information and the primary challenge is creating a framework that is effective at modeling relatively sparse data from multiple cell types. The rather narrow purview of biochemical models

also makes it likely that many important responses are missed because they are not measured. The future clearly lies in creating hybrid models that fuse biochemical data on immediate-early signaling with data on sequence variation, gene expression, and transcription factor binding. Such models would provide unique insight into mechanisms of oncogenic transformation and would have practical uses in drug discovery and tumor classification. For example, it has been shown that generic PINs and PKNs represent valuable prior knowledge for tumor classification from transcriptional profiles (47), and it seems likely that more accurate tumor-specific logical models or hybrid "interactomes" would prove even more useful in this context.

#### Disclosure of Potential Conflicts of Interest

No potential conflicts of interest were disclosed.
